& Jeroen A. M. van Gool

## Summary

This interim report comprises new zircon U-Pb geochronology data for rock samples collected during a 2005 mapping campaign on Ujarassuit Nunaat in the Nuuk region, southern West Greenland. Zircons separated from the samples were analysed for U-Pb isotopes using the GEUS in-house laser ablation-sector field-inductively coupled plasma-mass spectrometer facility. The findings shed new light on the timing of formation and metamorphism of supracrustal belts in this area, and on the regional orthogneisses.

Mesoarchaean (or older) orthogneisses exist throughout the Ujarassuit area. The amphibolitic supracrustal belt in Ujarassuit area 8 is intruded by c. 3010 Ma leucogranitic gneiss. Likewise, supracrustal rocks in Ujarassuit area 6 are intruded by a  $\geq$  3025 Ma tonalitic leucogneiss. These supracrustal belts were therefore deposited prior to those times. A relatively old magmatic component of a biotite-felsic orthogneiss from area 4 was emplaced at  $\geq$  2974 Ma (sample 498864), confirming data of C.R.L. Friend (pers. comm.) and furthering the extent of (probable) Mesoarchaean orthogneisses in the Ujarassuit area.

Three samples of weakly deformed felsic orthogneisses from Ujarassuit area 9 (sample 498420), area 6 (sample 498496), and area 4 (sample 498877) represent relatively young phases of magmatism. Emplacement is constrained to c. 2870 Ma,  $\geq$  2750 Ma and  $\geq$  c. 2825 Ma respectively. They are deformed by 10 kilometre-scale folds (Hollis et al. 2006).

A biotite orthogneiss representative of gneisses from within Ujarassuit area 5 yielded evidence for an emplacement age of  $\geq$  c. 3373 Ma, where these rocks were previously mapped as Nûk gneiss (c. 3070 Ma). Results from more structurally complex gneisses further east, across a mapped lithological boundary, confirmed a previous interpretation that those are Eoarchaean gneisses ( $3872 \pm 43$  Ma; Chadwick and Coe 1988).

Intermediate composition amphibolites of inferred volcanic origin from Ujarassuit area 4 (sample 498892) and area 5 (sample 498945) yielded evidence for deposition probably at around 3400 Ma. These are the first recorded supracrustal rocks of this age in the Nuuk region and further work should be done to investigate their timing of formation and regional significance. The same rocks from area 5 (sample 498945) contain metamorphic zircon dated at  $3056 \pm 5$  Ma, possibly related to the emplacement of Nûk gneisses at this time.

Samples from within the supracrustal belts in area 9 (sample 498422), area 8 (sample 498447), and area 1 (sample 498803) yielded metamorphic zircon dated at  $2598 \pm 10$  Ma,  $2617 \pm 6$  Ma,  $2609 \pm 14$  Ma respectively. These indicate that a Neoarchaean metamorphic event affected a large part of the Ujarassuit area. Similar metamorphic ages (and also up to c. 2700 Ma) were previously established for samples from Storø (Hollis 2005) – a c. 2700 Ma amphibolite facies event is known to have affected most of the Nuuk region (Nutman et al. 1989, Friend et al. 1996).

Results from central Storø show that the felsic orthogneiss structurally underlying the supracrustal belt on central Storø (sample 496516) is Mesoarchaean, emplaced at c. 3050 Ma. This is consistent with data from Hollis (2005) for a tonalitic gneiss intrusive into the metagabbro-anorthosite that lies structurally beneath the supracrustal belt on Storø.

# Introduction

The U-Pb zircon geochronology data presented here were obtained in 2006 for samples collected during a 2005 mapping campaign in the Ujarassuit area (see Hollis et al. 2006). The mapping was carried out by Ali Polat and Carlos Ordóñez (University of Windsor), Nigel Kelly (University of Edinburgh), Ole Stecher, Jeroen van Gool, and Susanne Schmid (GEUS). This mapping work forms part of an ongoing GEUS program to understand the geological setting of formation and tectonothermal evolution of supracrustal rocks in the Nuuk region, southern West Greenland (see also Appel et al. 2003, Hollis et al. 2004, Hollis 2005, Hollis et al. 2006, Nielsen et al. 2004, Stensgaard et al. 2005). A summary of the regional geology is given in Appel et al. (2003) and Hollis et al. (2004).

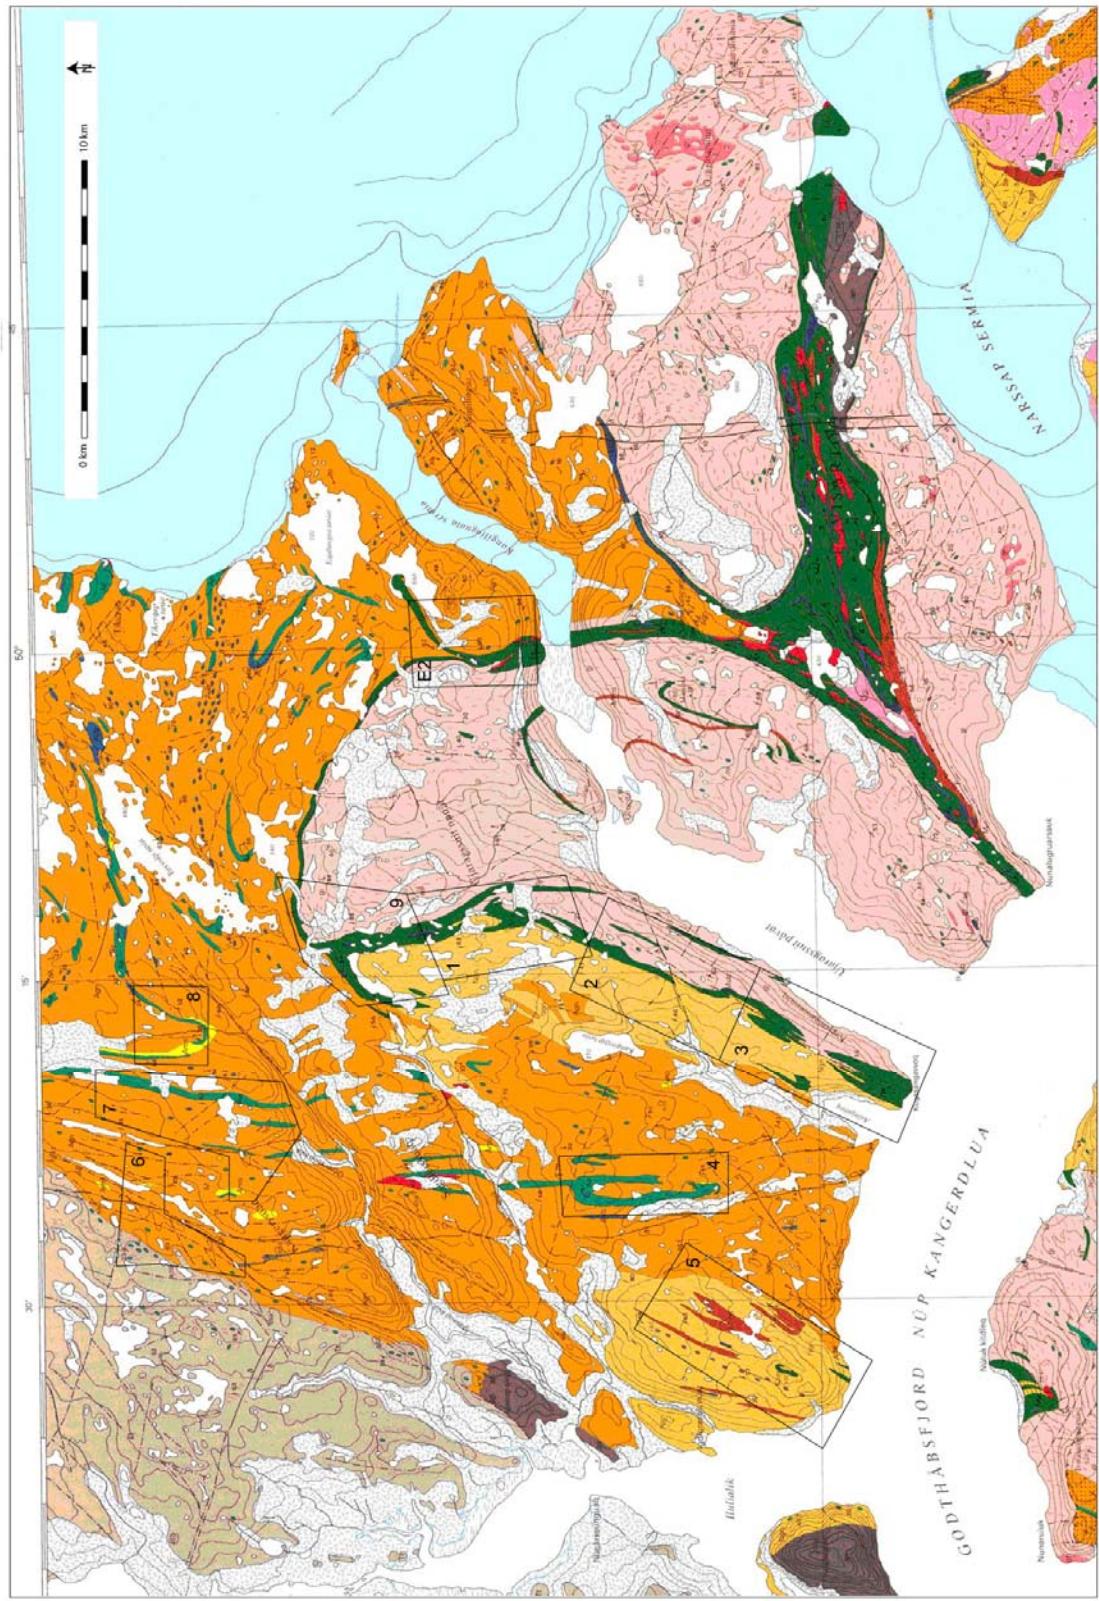

The complete tabulated data are presented in Appendix 1. Each analysed sample is discussed in the text and relevant data is presented in age plots. The areas mapped (areas 1–9), referred to in the text in relation to sample locations, are shown in Figure 1. The sample localities along with summary age information are shown in Figs 2–7 and in Table 1.

# Geochronology

## Sample preparation

Rock samples were typically hammered into small, centimetre- to decimetre-scale fragments on the outcrop. This was done to avoid potential contamination by breaking up the sample in the laboratory. Remaining large samples were sawed into small pieces, crushed to a coarse powder in a steel ring mill, and sieved to obtain the  $< 400 \mu\text{m}$  fraction. Powders were separated by hand-panning and the heavy-fraction was further separated where required using a magnet. The non-magnetic heavy fraction obtained typically included phases such as zircon, titanite, rutile, and sulphide minerals.

Individual zircon grains were hand-picked from the heavy mineral fraction under an optical binocular microscope. These were mounted in rows on double-sided sticky tape. The mounted zircons were then set in one inch diameter circular epoxy mounts, which were then ground to reveal the mid-sections of the zircon grains, and polished to one micron grade.

The polished zircons were imaged using cathodoluminescence (CL) or back-scattered electron (BSE) imaging employing a Philips XL 40 scanning electron microscope at GEUS. Images were used to identify the internal morphology of grains (influenced by, for example, growth, resorption, alteration, or metamorphism) to select areas of interest for analysis.

## Laser ablation – inductively coupled plasma – sector field mass spectrometry (LA-SF-ICPMS) methodology

The LA-SF-ICPMS uses a focussed laser beam to ablate a small amount of a sample contained in an air-tight sample cell. The ablated material is transferred to a mass-spectrometer in a carrier gas via tygon tubing for isotopic quantification. For the spot diameter ( $30 \mu\text{m}$ ) and ablation times (45 s) used in this study, the ablated masses of zircon were approximately 200–500 ng.

The laser ablation system used at GEUS was a NewWave Research/Merchantek UP213 equipped with a frequency quintupled Nd-YAG laser emitting at a wavelength of 213 nm. The nominal pulse width of the laser is 5 ns with a pulse-to-pulse stability of 2 % RSD. The laser was operated at a repetition rate of 10 Hz and a nominal energy output of 44 %, corresponding to a laser fluency of  $8 \text{ J cm}^{-2}$ . All data were acquired with a single spot analysis on each individual zircon grain with a beam diameter of  $30 \mu\text{m}$  producing a spot with depth of c.  $15 \mu\text{m}$ . Samples and standards were held in a low-volume ablation cell designed in order to achieve fast flush-out times and stable, spike-free, time-resolved signals. He was used to flush the sample cell and was mixed downstream with the Ar sample gas of the

mass-spectrometer. The washout time for this configuration was approximately 20 s. All sample mounts were rigorously cleaned before introduction into the sample cell to remove surface Pb contamination.

The ablated material was analysed with an Element2 (ThermoFinnigan, Bremen) single-collector double focusing magnetic sector ICPMS equipped with a fast field regulator for increased scanning speed. The total acquisition time for each analysis was 100 s with the first 30 s used to measure the gas blank. The instrument was tuned to give large, stable signals for the  $^{206}\text{Pb}$  and  $^{238}\text{U}$  peaks, low background count rates (typically around 300 counts per second for  $^{207}\text{Pb}$ ) and low oxide production rates ( $^{238}\text{U}^{16}\text{O}/^{238}\text{U}$  generally below 2 %). All measurements were performed in low resolution mode using electrostatic scanning (E-scan) with the magnetic field resting at mass  $^{202}\text{Hg}$ . The following masses were measured:  $^{202}\text{Hg}$ ,  $^{204}(\text{Pb} + \text{Hg})$ ,  $^{206}\text{Pb}$ ,  $^{207}\text{Pb}$ ,  $^{208}\text{Pb}$ ,  $^{232}\text{Th}$ ,  $^{235}\text{U}$ , and  $^{238}\text{U}$ . All data were acquired on four samples per peak with a sampling time of 10 ms for most isotopes (except  $^{204}(\text{Pb} + \text{Hg})$  and  $^{207}\text{Pb}$ , which were measured for 40 ms) and a settling time of 1 ms for each isotope. Mass  $^{202}\text{Hg}$  was measured to monitor the  $^{204}\text{Hg}$  interference on  $^{204}\text{Pb}$  (using a  $^{202}\text{Hg}/^{204}\text{Hg}$ -ratio of 4.36). For net intensities for mass  $^{204}\text{Pb}$ , corrected for  $^{204}\text{Hg}$ , above the limit of detection these analyses were discarded in favour of performing a common Pb-correction. The laser induced elemental fractionation and the instrumental mass bias on measured isotopic ratios were corrected by matrix-matched external standardisation using the GJ-1 zircon standard (Jackson et al. 2004). Samples were analysed in sequences where six standards are analysed initially, followed by ten samples, followed by three standards, and then repeating ten unknowns followed by three standards.

The raw data were exported in ASCII format and processed using Excel-based in-house age data reduction spreadsheets. Age calculations for populations were carried out using the IsoPlot/Ex 3.0 excel add in (Ludwig 2003).

## Results

In the following LA-SF-ICPMS U-Pb zircon dating results are given for each sample analysed.  $^{207}\text{Pb}/^{206}\text{Pb}$  weighted mean ages were calculated using the Excel add-in IsoPlot/Ex version 3.0 (Ludwig 2003). All ages in the text are quoted with two sigma uncertainties. All tabulated age data are presented in Appendix 1. All data that are < 10% discordant are presented on  $^{206}\text{Pb}/^{238}\text{U}$ - $^{207}\text{Pb}/^{235}\text{U}$  Wetherill concordia diagrams. Error ellipses on diagrams are shown with one sigma uncertainties and where relevant  $^{207}\text{Pb}/^{206}\text{Pb}$  ages are shown on weighted mean age plots with two sigma uncertainty. The mean squared weighted deviates (MSWD) is used as a convenient measure of scatter in the data. An MSWD = 1 indicates that the scatter in the data is equal to that predicted from the analytical error. MSWD > 1 indicates greater scatter than would be predicted from analytical errors alone, whereas MSWD < 1 indicates less scatter than would be predicted from analytical errors alone. Thus MSWD significantly greater than 1 indicates that there is a real difference in ages of the grains analysed.

### 496513

Collector: Dave Coller

Lithology: Felsic sheet cutting dominant felsic orthogneiss immediately underlying supracrustal belt on central Storø.

Location: central east Storø

Locality: dcl2005-152, 64°27.812'N, -50°55.612'W

Aim: minimum age of gneissic banding in dominant felsic orthogneiss structurally underlying the supracrustal belt on Storø.

Age of emplacement: c. 2715 Ma? or 2981 Ma?

The zircons are typically 150–300 µm in length with aspect ratios 1:2 to 1:3, typically prismatic. Around half have CL-bright homogeneous or oscillatory-zoned cores, the remainder are CL-dull and fairly homogeneous. Those with CL-bright cores often have CL-dark homogeneous rims up to 60 µm wide.

Twenty-three spots in 23 grains were analysed. Seven analyses with high common Pb were discarded. The zircons have 42–910 ppm U and Th/U typically 0.22 to 1.25. The younger grains tend toward higher U contents. Sixteen concordant analyses give an age range of  $3136 \pm 27$  to  $2548 \pm 16$  Ma with no distinct age populations present. A cluster of four ages at c. 2981 Ma and also at 2715 Ma may represent the emplacement age, though this is unclear as neither can be linked to distinct zircon morphologies, and this supposition is based only on the relatively high proportions of grains of these ages represented.

This felsic sheet cuts the gneissic fabric in the dominant felsic orthogneiss on central north Storø. It may have been emplaced at either c. 2981 or 2715 Ma, though neither age is well-defined.

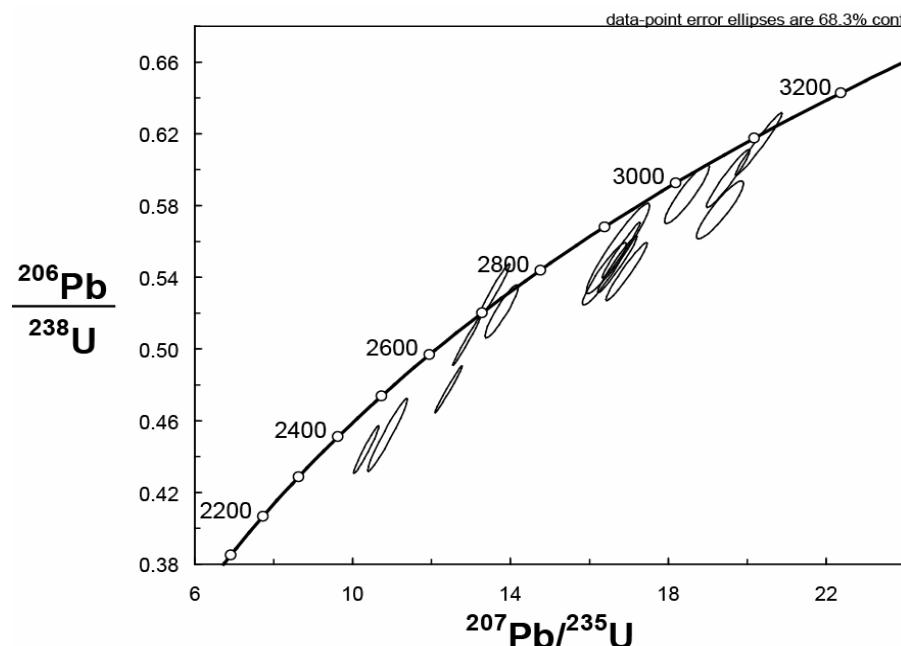

Figure 8. 496513  $^{206}\text{Pb}/^{238}\text{U}$ - $^{207}\text{Pb}/^{235}\text{U}$  concordia diagram.

**496516**

Collector: Dave Coller

Lithology: Felsic orthogneiss immediately north of the anorthosite on central Storø.

Location: central east Storø

Locality: dcl2005-186, 64°27.397'N, -50°58.346'W

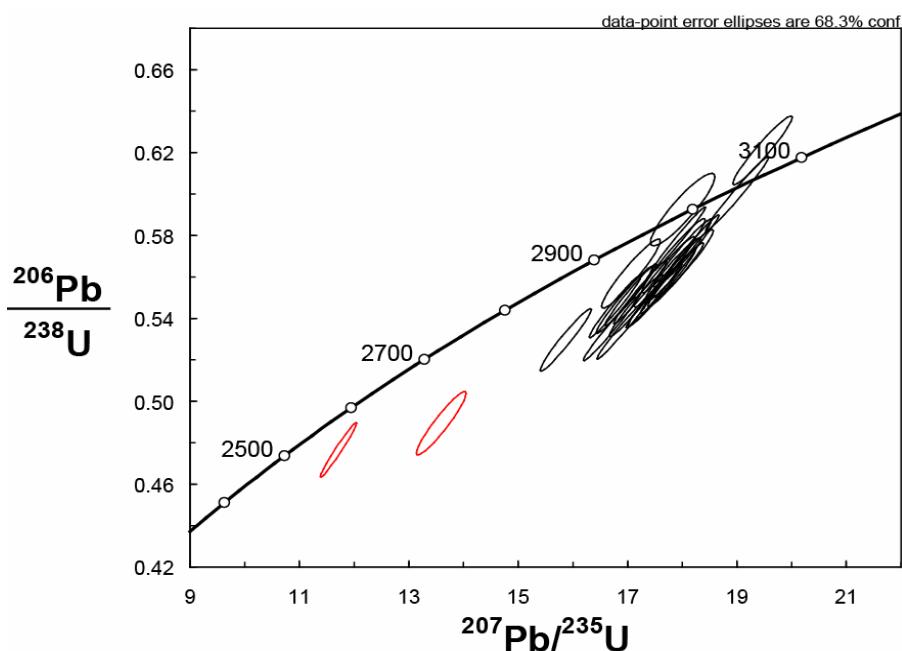

Aim: emplacement age of dominant orthogneiss structurally underlying the supracrustal belt on central Storø

Age of emplacement:  $3045 \pm 13$  Ma (upper-intercept age, MSWD, 3.1, n = 16 of 25)

The zircons are typically 100–300  $\mu\text{m}$  in length with aspect ratios of 1:1 to 1:2 and commonly prismatic. Most show well-defined closely-spaced oscillatory zonation. A minority show sector zonation. Many grains have thin (up to 30  $\mu\text{m}$ ) CL-dull rims.

Twenty-five spots in 21 grains were analysed. Ages range from  $3060 \pm 13$  to  $2637 \pm 12$  Ma. Oscillatory-zoned cores have 16–100 ppm U and Th/U of 0.45–0.86. There is a trend toward lower Th/U for cores younger than c. 3020 Ma, and also for rim analyses, which reach a minimum of 0.05 for the youngest rim age. Sixteen oscillatory-zoned cores and one sector zoned core, all with relatively high Th/U, give a poorly defined age of  $3045 \pm 13$  Ma (upper-intercept age, MSWD, 3.1, n = 16 of 25). This age also agrees well with the most concordant (and therefore probably the most reliable) oscillatory zoned core analysis, which is  $3050 \pm 11$  Ma (0.4% discordant).

This sample was collected as representative of the dominant felsic orthogneiss structurally underlying the supracrustal belt on central east Storø. The data show it is a Mesoarchaean rock emplaced at c. 3050 Ma, based on analyses of oscillatory-zoned cores that appear to have undergone some degree of recrystallisation based on a trend toward lower Th/U with decreasing age.

**Figure 9.** 496516  $^{206}\text{Pb}/^{238}\text{U}$ - $^{207}\text{Pb}/^{235}\text{U}$  concordia diagram.

## 496519

Collector: Dave Coller

Lithology: highly-deformed aplitic sheet within cataclastic rock, post-dating the onset of cataclastic deformation, within a broad zone of deformation on Sermitsiaq.

Location: Sermitsiaq

Locality: dcl2005-284, 64 18.289°N, -51 20.243°W

Aim: minimum age constraint on the onset of cataclastic deformation within the shear zone on Sermitsiaq.

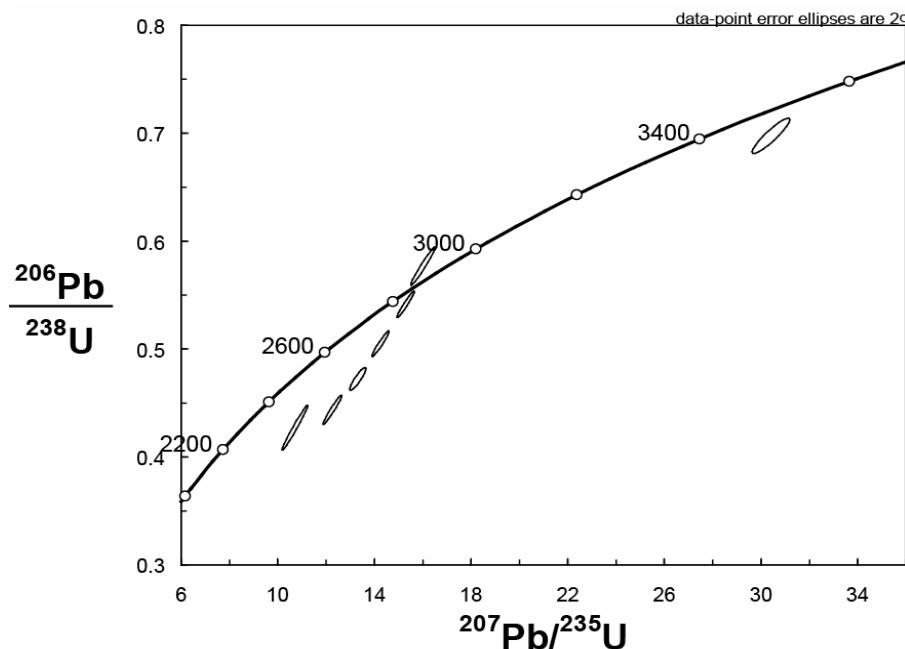

Age of emplacement: ?  $\leq$  c. 2850 Ma (n = 5 of 8)

Age of metamorphism: c. 2670 Ma (n = 1 of 8)

This sample is dominated by completely metamict grains, on which LA-SF-ICPMS analysis was not attempted. The remaining few grains are typically 100–200  $\mu\text{m}$  in length with aspect ratios 1:1 to 1:3, commonly prismatic. They have weakly- to well-defined oscillatory zonation and a few have thin CL-dark rims.

Twelve spots in 9 grains were analysed. Four analyses with high common Pb were strongly discordant and were discarded. The zircons have 6–1307 ppm U, with a correlation between increasing U content with decreasing age. Ages range from  $3662 \pm 1968$  Ma (very low-U and Pb) to  $2670 \pm 25$  Ma (very high-U and Pb). The data fall into two main groups that are not strongly linked to distinct zircon morphologies. A single old grain produced the only two Eo- to Palaeoarchaean ages of  $3662 \pm 1968$  Ma and  $3551 \pm 26$  Ma. Five grains form a rough population at  $2853 \pm 36$  Ma (upper-intercept age, MSWD 3.8, n = 5 of 8). A single homogeneous grain has a much younger age of  $2670 \pm 25$  Ma and very high U (1307 ppm) and low Th/U of 0.09.

This highly-deformed aplitic sheet was collected from within a zone of cataclastic deformation within the shear zone on Sermitsiaq. The timing of emplacement of the dyke post-dates the onset of cataclasis as the dyke cross-cuts but is deformed by the cataclastic deformation. The timing of emplacement is not at all clear from the age data. The c. 2850 Ma age of the majority of the grains analysed (five grains) is not well-defined and these may also be inherited from metasedimentary rocks on Sermitsiaq known to carry detrital zircons of this age (see Hollis 2005). The single c. 3600 Ma grain is interpreted as inherited from rocks of the Itsaq gneiss complex, also present locally. The single 2670 Ma grain may represent the timing of emplacement as it has very high U (and low Th/U), typical of late-stage melts. It is possible that the dominant metamict grains (not analysed) – which are by inference high-U – are also this age. This age corresponds with the timing of known regional amphibolite facies metamorphism and partial melting (eg. Nutman et al. 1989, Friend et al. 1996, Hollis 2005).

**Figure 10.** 496519  $^{206}\text{Pb}/^{238}\text{U}$ - $^{207}\text{Pb}/^{235}\text{U}$  concordia diagram.

#### 498420

Collector: Jeroen van Gool

Lithology: weakly-foliated biotite-bearing granodioritic to tonalitic gneiss

Location: Ujarassuit area 9

Locality: jvg2005-088, 64 53.202°N, -50 14.203°W

Aim: age of youngest phase of orthogneisses and maximum constraint on formation of regional F3 folds

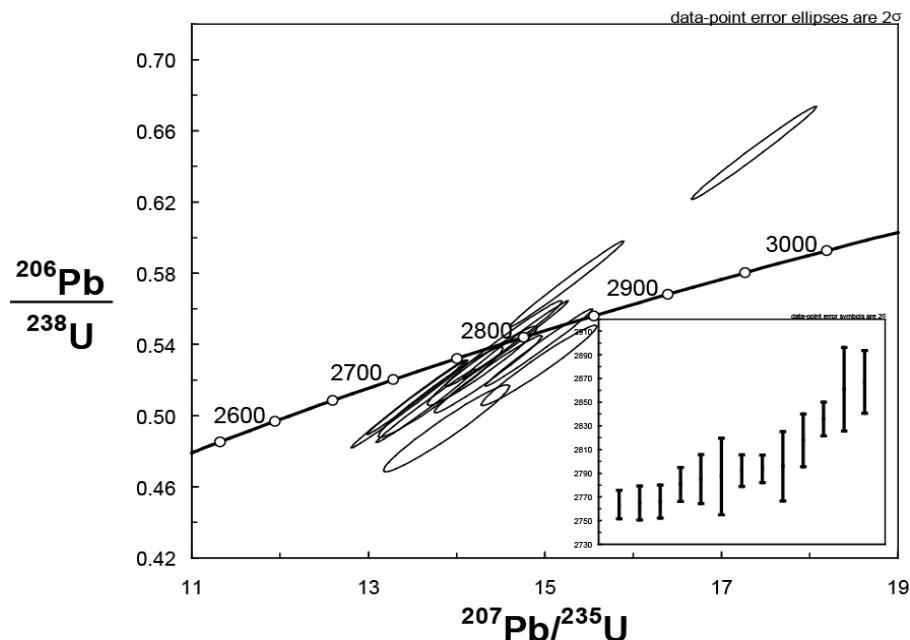

Age of emplacement:  $\leq$  c. 2870 Ma

The zircons are 50–150  $\mu\text{m}$  with aspect ratios typically 1:2 to 1:3. All grains are homogeneous or show patchy zonation with indications of recrystallisation.

Twenty-one spots in 20 grains were analysed. Eight analyses with high common Pb were strongly discordant and were discarded. The zircons have 6–1307 ppm U with Th/U of 0.27–2.71. The data show a spread in ages from c. 2867 to 2764 Ma. The spread in ages do not show any correlation with chemistry or morphology.

The sample is representative of the youngest phase of felsic orthogneiss present in the Ujarassuit Nunaat – east region. This lithology holds a gneissic fabric, but post-dates the main phase of fabric formation in the regional felsic orthogneisses. Given the spread in age data it is possible that Pb-loss may have affected this sample after emplacement and that the oldest grain –  $2867 \pm 27$  Ma (< 2% discordant) – falls close to the emplacement age. Alternatively the oldest 3 grains, which fall away from the main age group, may be inherited and the cluster at c. 2780 Ma may reflect the timing of emplacement. Therefore the regional

gneissic fabric is constrained to being older than c. 2780 Ma, and the kilometre-scale F3 folding must be younger than at least c. 2870 Ma.

**Figure 11.** 498420  $^{206}\text{Pb}/^{238}\text{U}$ - $^{207}\text{Pb}/^{235}\text{U}$  concordia diagram and inset  $^{207}\text{Pb}/^{206}\text{Pb}$  age plot.

#### 498422

Collector: Jeroen van Gool

Lithology: homogeneous medium-grained hornblende gneiss, possibly originally a gabbro, which forms a part of the mafic amphibolite sequence, or is possibly a later intrusion

Location: Ujarassuit area 9

Locality: jvg2005-083, 64 53.353°N, -50 13.699°W

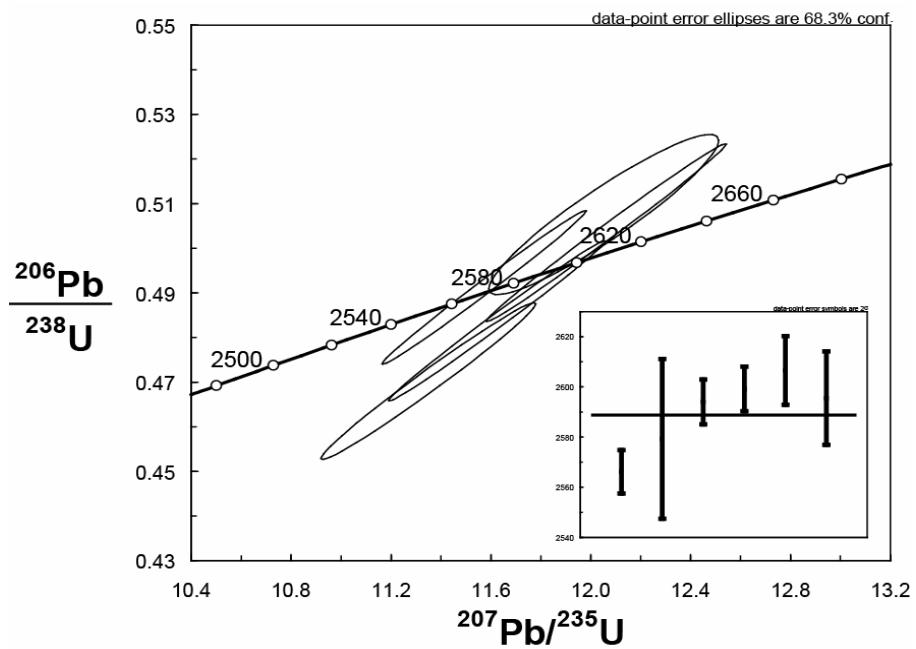

Aim: depositional or minimum age of the supracrustal sequence in Ujarassuit area 9

Age of metamorphism:  $2598 \pm 10$  Ma (MSWD 1.3, n = 5)

Only a few small zircons were obtained from this sample. They are 100–150  $\mu\text{m}$  in length with aspect ratios typically 1:1 to 1:2. All grains are homogeneous.

Six spots in 6 grains were analysed. None contained significant common Pb. Concordant ages (< 3% discordant, n = 5) range from  $2607 \pm 14$  to  $2566 \pm 9$  Ma with U contents of 260–749 ppm and Th/U of 0.02–0.11. Four of five analyses define a population with some significant spread in ages at  $2598 \pm 10$  Ma (weighted average, MSWD 1.3, n = 5).

The sample was collected from a homogeneous hornblende gneiss, possibly originally a gabbro, within the mafic amphibolite sequence in the Ujarassuit Nunaat–east area. The low Th/U and homogeneous morphologies are consistent with a  $2598 \pm 10$  Ma metamorphic age for this sample and therefore for the supracrustal belt as a whole.

**Figure 12.** 498422  $^{206}\text{Pb}/^{238}\text{U}$ - $^{207}\text{Pb}/^{235}\text{U}$  concordia diagram and inset  $^{207}\text{Pb}/^{206}\text{Pb}$  age plot.

#### 498447

Collector: Jeroen van Gool

Lithology: Homogeneous hornblende-bearing quartz-dioritic gneiss that forms an integral part of the supracrustal unit (does not post-date the supracrustal rocks).

Location: Ujarassuit area 8

Locality: jvg2005-187, 64 57.044°N, -50 17.446°W

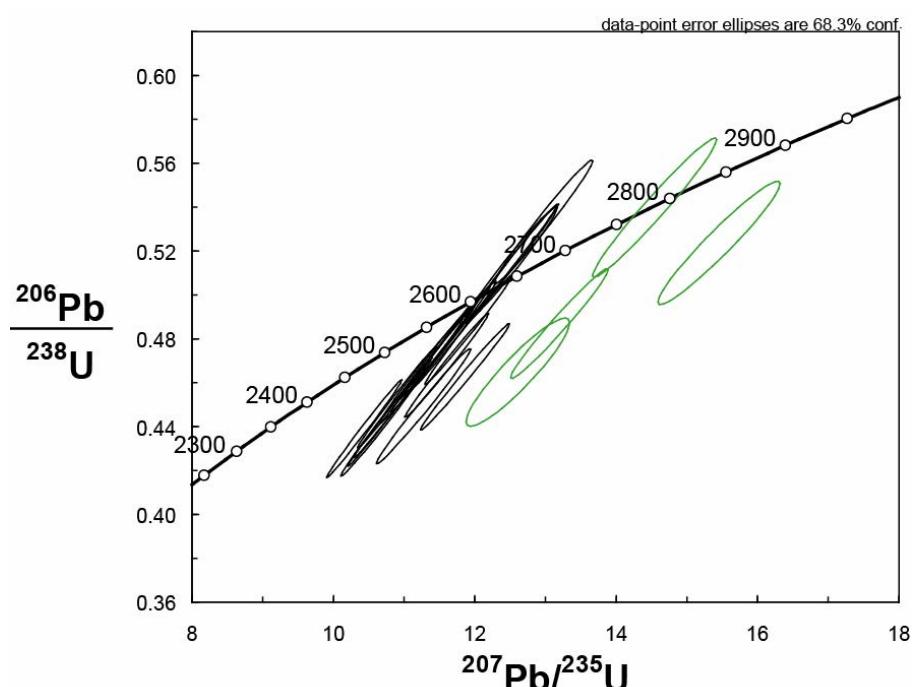

Aim: age of formation of (at least part) of the Ujarassuit Nunaat area 8 supracrustal belt

Age of metamorphism:  $2617 \pm 6$  Ma (upper-intercept age, MSWD 0.35, n = 12 of 17)

The zircons are 50–150 µm with aspect ratios typically 1:1 to 1:2.5. Approximately half of the grains have oscillatory-zoned cores with homogeneous rims (up to 30 µm wide). The remainder are completely homogeneous and commonly equant, consistent with growth during metamorphism.

Thirty spots in 30 grains were analysed. Eight analyses with high common Pb were discarded. Four oscillatory-zoned cores yielded ages between  $2936 \pm 34$  Ma and  $2707 \pm 14$  Ma with U contents of 99–237 ppm and Th/U of 0.25–0.98. The remaining 17 analyses – 16 homogeneous cores and one homogeneous rim – yielded ages from  $2671 \pm 18$  Ma to  $2581 \pm 11$  Ma with U contents of 79–265 ppm and Th/U of 0.06–0.18. These relatively low Th/U ratios, coupled with the distinct homogeneous morphologies, are consistent with zircon growth and/or recrystallisation during metamorphism. Thirteen of the 17 of these relatively young grains yield a population at  $2617 \pm 6$  Ma (upper-intercept age, MSWD 0.35, n = 12 of 17, 3 oldest and one youngest grain excluded), interpreted as the age of metamorphism.

The age of emplacement of this rock is not clear from the data available as the 4 cores yielded ages spanning the range  $2936 \pm 34$  Ma and  $2707 \pm 14$  Ma. It is possible that the youngest of these ages represents a mixed core-rim age and may therefore be geologically meaningless. The age of metamorphism of this rock is quite well-constrained to  $2617 \pm 6$  Ma, and correlates with amphibolite-facies metamorphism around this time known from the central Godthåbsfjord area and therefore influencing a wide region (eg. Hollis 2005). This is also consistent with the metamorphic age derived from sample 498422 (see above and Figs 1 and 2, area 9).

**Figure 13.** 498447  $^{206}\text{Pb}/^{238}\text{U}$ - $^{207}\text{Pb}/^{235}\text{U}$  concordia diagram and inset  $^{207}\text{Pb}/^{206}\text{Pb}$  age plot.

#### 498452

Collector: Jeroen van Gool

Lithology: Medium- to coarse-grained leucogranite intruded into amphibolitic supracrustal rocks in Ujarassuit area 8.

Location: Ujarassuit area 8

Locality: jvg2005-189, 64 57.082°N, -50 17.616°W

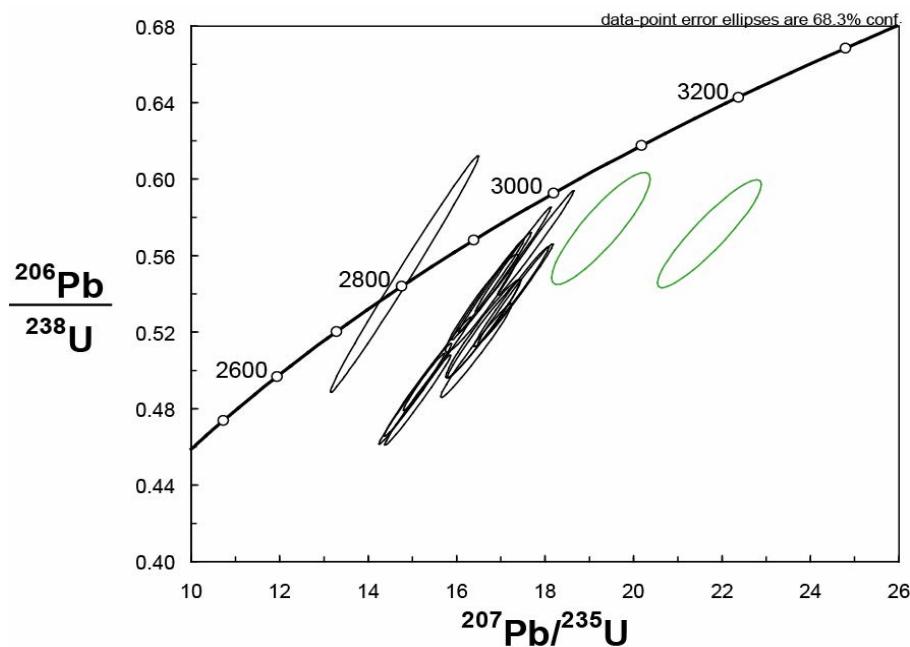

Aim: minimum age of formation of the supracrustal belt in Ujarassuit area 8 and minimum age of gneissic fabric preserved in the supracrustal rocks.

Age of emplacement:> c. 3010 Ma

The zircons are typically 50–100 µm with aspect ratios typically 1:2 to 1:3. Most grains have oscillatory-zoned cores, some with CL-dark homogeneous rims up to 60 µm wide.

Thirty-one spots in 27 grains were analysed. Nine analyses with high common Pb were discarded. The remaining 22 grains yield ages between  $3338 \pm 45$  Ma and  $2787 \pm 26$  Ma with U contents of 67–369 ppm and Th/U of 0.32 to 1.20. There is no significant correlation between zircon ages, chemistry, and morphology. Seven analyses of six oscillatory-zoned cores and one oscillatory-zoned rim form a cluster of ages at c. 3010 and another 7 ages for oscillatory-zoned and homogeneous cores range from 3026–3077 Ma with significant spread in the data. Two older core analyses of  $3338 \pm 45$  Ma and  $3141 \pm 57$  Ma may be inherited grains. A single analysed homogeneous rim gives an age of  $2787 \pm 26$  Ma.

This is a sample of a leucogranite intrusive into amphibolitic supracrustal rocks (of possibly volcanic origin) within Ujarassuit area 8. The age population at c. 3010 Ma defined by 7 analyses may represent a real geological event, or may alternatively represent Pb-loss from older grains, given the significant spread in ages for another 7 grains from 3026–3077 Ma. We therefore interpret the c. 3010 Ma age as a minimum age of emplacement. The data provide a minimum constraint on the age of deposition of the supracrustal belt of  $\geq$  c. 3010 Ma.

**Figure 14.** 498452  $^{206}\text{Pb} / ^{238}\text{U}$ - $^{207}\text{Pb} / ^{235}\text{U}$  concordia diagram.

#### 498481

Collector: Jeroen van Gool

Lithology: late aplitic dyke within Tasersuaq pluton representing the last intrusive phase

Location: Ujarassuit area 6, Tasersuaq pluton

Locality: jvg2005-287, 64 58.741°N, -50 25.764°W

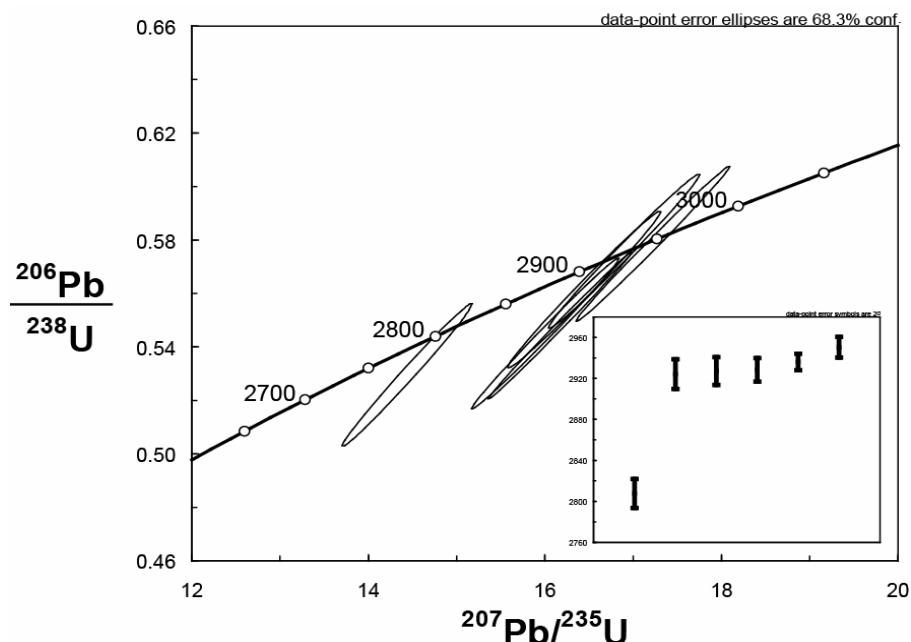

Aim: minimum age of deformation of the Tasersuaq pluton

Age of emplacement: ?  $2936 \pm 13$  Ma (MSWD 3.5, n = 5 of 6)

This sample yielded very few zircons, all of which are  $\leq 100 \mu\text{m}$  in length, with aspect ratios of typically 1:2 and prismatic. All are oscillatory-zoned and four of the five grains give a quite dark CL response, while the last has a bright CL response.

Six spots in 7 grains were analysed. One analysis with high common Pb was discarded. The four CL-dark grains give a rough age population of  $2936 \pm 13 \text{ Ma}$  (MSWD 3.5,  $n = 5$  of 6) with U contents of 265–469 ppm and Th/U of 0.48–1.68. The one CL-bright grain is  $2808 \pm 14 \text{ Ma}$  with relatively low U content (65 ppm) and Th/U (0.39).

The sample was collected from a late aplitic dyke that post-dates all deformation in the Tasersuaq pluton and thus provides a minimum age constraint on deformation. There are too few zircon grains from this sample to place much emphasis on the inferred age constraints, and also some ambiguity in the age data itself. It is probable that the four  $2936 \pm 13 \text{ Ma}$  grains represent the timing of emplacement of the dyke, though the age is poorly constrained. If so, this would indicate that no further deformation events affected the Tasersuaq pluton after c. 2936 Ma, consistent with the findings of Garde et al. (2000).

**Figure 15.** 498481  $^{206}\text{Pb}/^{238}\text{U}$ - $^{207}\text{Pb}/^{235}\text{U}$  concordia diagram and inset  $^{207}\text{Pb}/^{206}\text{Pb}$  age plot.

**498496**

Collector: Jeroen van Gool

Lithology: Strongly deformed homogeneous light grey tonalitic biotite orthogneiss, which is discordant to an older gneissic fabric

Location: Ujarassuit area 6

Locality: jvg2005-316, 64 58.193°N, -50 23.122°W

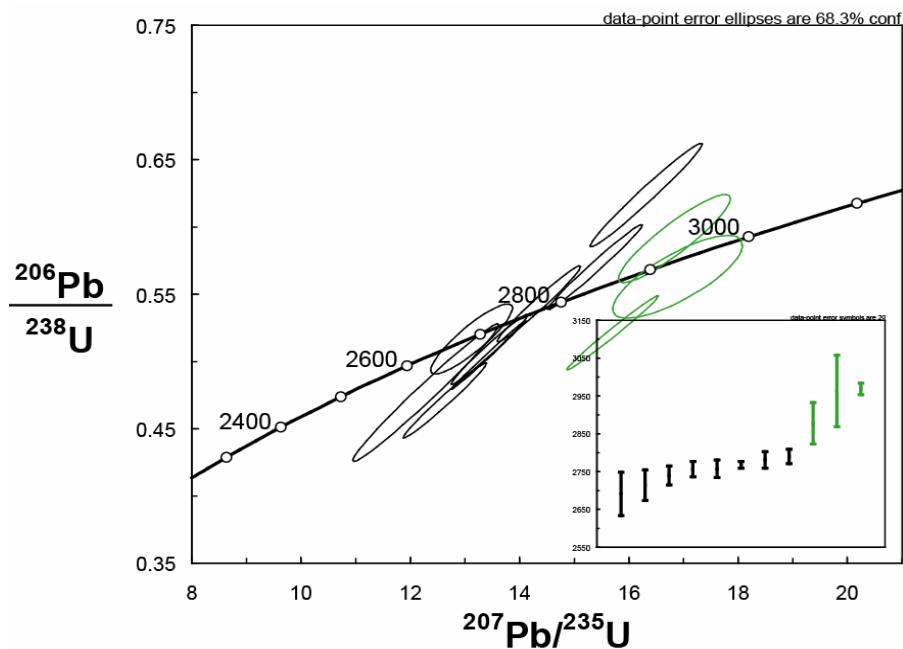

Aim: Timing of relatively young phase of tonalitic magmatism

Age of emplacement:  $\geq 2750$  Ma

The zircons are 100–200  $\mu\text{m}$  in length with aspect ratios typically 1:3 to 1:4, and prismatic. A few have metamict cores and all are CL-dark. BSE imaging shows that most have oscillatory zonation or relict oscillatory zonation. Many have concentric and radial fracturing around high-U cores. Some of these fractures show partial recrystallisation features. The majority are homogeneous, a few with some poorly-defined oscillatory zonation and a few with wide BSE bright rims around darker cores.

Thirty spots in 28 grains were analysed. Nineteen with high common Pb were discarded. The high proportion of analyses showing high common Pb is attributed to the high degree of metamictisation (high-U). Of the remaining 11 analyses ages range from  $2969 \pm 16$  to  $2691 \pm 58$  Ma, with U contents of 65–1183 ppm and Th/U of 0.12–0.91. The three oldest grains are  $2969 \pm 16$ ,  $2963 \pm 95$ , and  $2878 \pm 55$  Ma. Eight younger grains form a cluster of ages with significant spread at c. 2750 Ma. The youngest grain, at  $2691 \pm 58$  Ma, is by far the most U-rich.

The sample is representative of the youngest phase of magmatism recognised in the Ujarassuit region. This lithology post-dates formation of the main gneissic fabric in the dominant regional felsic gneisses and is deformed by the kilometre-scale F3 folds. It is possible that the poorly defined c. 2750 Ma age represents the timing of emplacement, though this is far from clear from the data. It does, however, give a minimum age constraint on the timing of emplacement age and on the development of the regional gneissic fabric, and a maximum constraint on the timing of regional F3 folding.

**Figure 16.** 498496  $^{206}\text{Pb}/^{238}\text{U}$ - $^{207}\text{Pb}/^{235}\text{U}$  concordia diagram and inset  $^{207}\text{Pb}/^{206}\text{Pb}$  age plot.

#### 498497

Collector: Jeroen van Gool

Lithology: foliated pegmatite that postdates the main gneissic fabric in the regionally-dominant orthogneiss and which is deformed by a subsequent shear-fabric.

Location: Ujarassuit area 6

Locality: jvg2005-317, 64 58.184°N, -50 23.765°W

Aim: minimum age constraint on formation of main regional gneissic fabric and maximum constraint on later phase/s of regional deformation

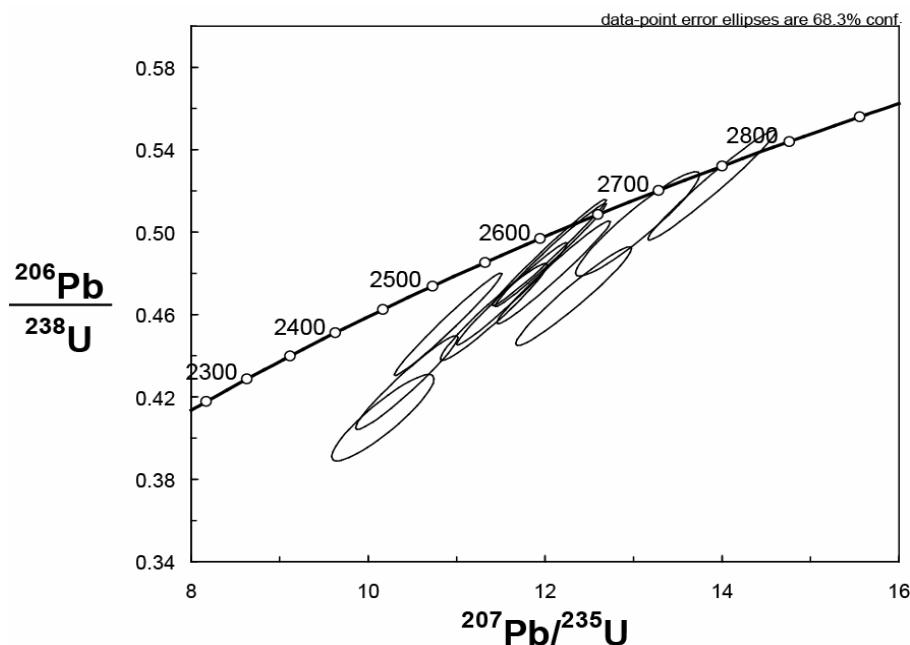

Age of emplacement:  $\geq$  c. 2645 Ma

The zircons are 80–150  $\mu\text{m}$  in length with aspect ratios typically 1:1 to 1:3, and commonly prismatic. Approximately one third are homogeneous, the remainder showing metamict and/or patchy heavily recrystallised cores.

Twenty spots in 20 homogeneous grains were analysed. Seven analyses with high common Pb were discarded. Ages range from  $2593 \pm 22$  to  $2765 \pm 23$  Ma with U contents of 221–1115 ppm and Th/U of 0.05–0.37. Six grains (not morphologically distinct) form a cluster of ages at c. 2645 Ma, however there is significant spread in the whole dataset.

The sample was collected from a pegmatite that post-dates the main gneissic fabric in the regionally dominant felsic gneisses, but which is also affected by later deformation. There is no significant relationship between zircon morphology and age data, nor with chemistry. As such the significant spread in age data is difficult to interpret. The youngest age group – c. 2645 Ma – can therefore be interpreted only as a minimum estimate of the age of em-

placement, which could have occurred significantly earlier. Therefore development of the main gneissic fabric is constrained to > c. 2645 Ma.

**Figure 17.** 498497  $^{206}\text{Pb}/^{238}\text{U}$ - $^{207}\text{Pb}/^{235}\text{U}$  concordia diagram and inset  $^{207}\text{Pb}/^{206}\text{Pb}$  age plot.

#### 498762

Collector: Jeroen van Gool

Lithology: Homogeneous tonalitic leucogneiss intrusive into supracrustal rocks, and representative of the dominant felsic orthogneisses in this area

Location: Ujarassuit area 6

Locality: jvg2005-294, 64 58.544°N, -50 24.344°W

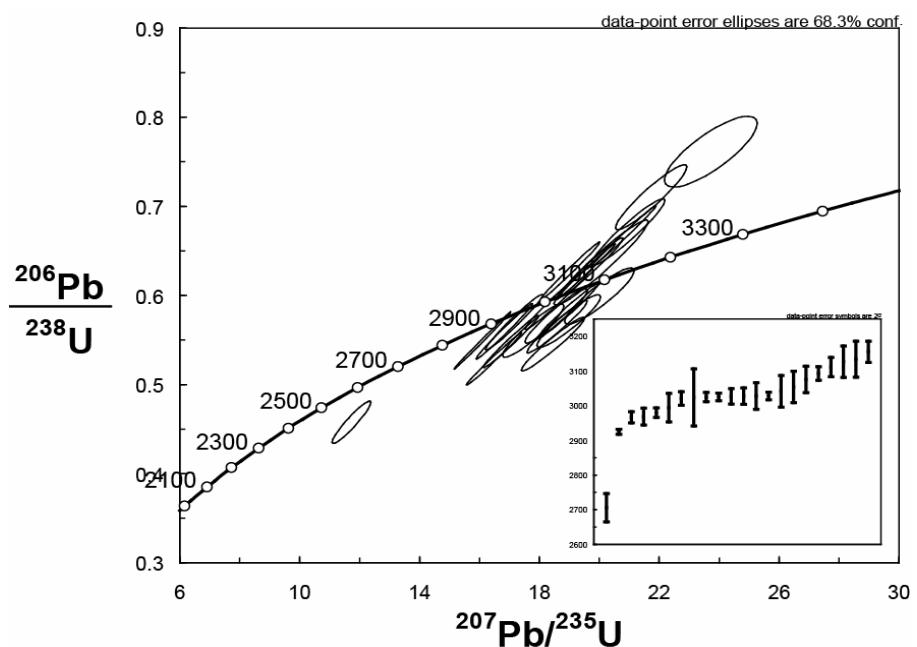

Aim: emplacement age of dominant regional orthogneiss in area 6.

Minimum age of emplacement:  $\geq 3025$  Ma

The zircons are 50–200 µm with aspect ratios typically 1:1.5 to 1:3, and prismatic. They commonly show oscillatory zonation. A few have metamict zones, often showing concentric and radial zonation with varying degrees of recrystallisation of fractures. A few have thin (up to 30 µm) homogeneous rims.

Thirty spots in 29 grains were analysed. Five analyses with high common Pb were discarded. Ages range from  $3155 \pm 31$  Ma to  $2706 \pm 41$  Ma, with U contents of 9–501 ppm and Th/U of 0.04–0.45. There is slight tendency toward lower Th/U and higher U contents with decreasing age, possibly indicative of some metamorphic recrystallisation of older grains, which is supported by morphological indications of recrystallisation and partial metamictisation. Around half of the analyses form a cluster of ages at c. 3025 Ma, though these grains are not morphologically or chemically distinct from the remaining grains, and thus the significance of this group is difficult to assess.

This sample is representative of the dominant regional tonalitic leucogneiss, which in this location is intrusive into supracrustal rocks in Ujarassuit area 6. A cluster of ages at c. 3025 Ma may represent the emplacement age, with older grains reflecting inheritance, though this is not certain. Alternatively emplacement may have occurred earlier and some Pb-loss may have occurred, producing the younger population at c. 3025 Ma. This is therefore a minimum age of emplacement for the igneous precursor to this orthogneiss, with the possibility that slightly older ages ( $3155 \pm 31$  to  $3054 \pm 45$  Ma) may be closer to the original age of emplacement. The minimum age of emplacement is consistent with the supracrustal belt in Ujarassuit area 6 being of a similar age to the Ivisaartoq supracrustal belt (eg. Friend and Nutman 2005).

**Figure 18.** 498762  $^{206}\text{Pb}/^{238}\text{U}$ - $^{207}\text{Pb}/^{235}\text{U}$  concordia diagram and inset  $^{207}\text{Pb}/^{206}\text{Pb}$  age plot.

#### 498803

Collector: Nigel Kelly

Lithology: Migmatitic garnet-biotite schist with centimetre-scale interlayering of leucosome and leucocratic zones with more biotite-rich material. Of inferred sedimentary or volcanic origin

Location: Ujarassuit area 1

Locality: nmk2005-018, 64 50.622°N, -50 12.786°W

Aim: age of detrital or volcanic zircon and therefore age of deposition

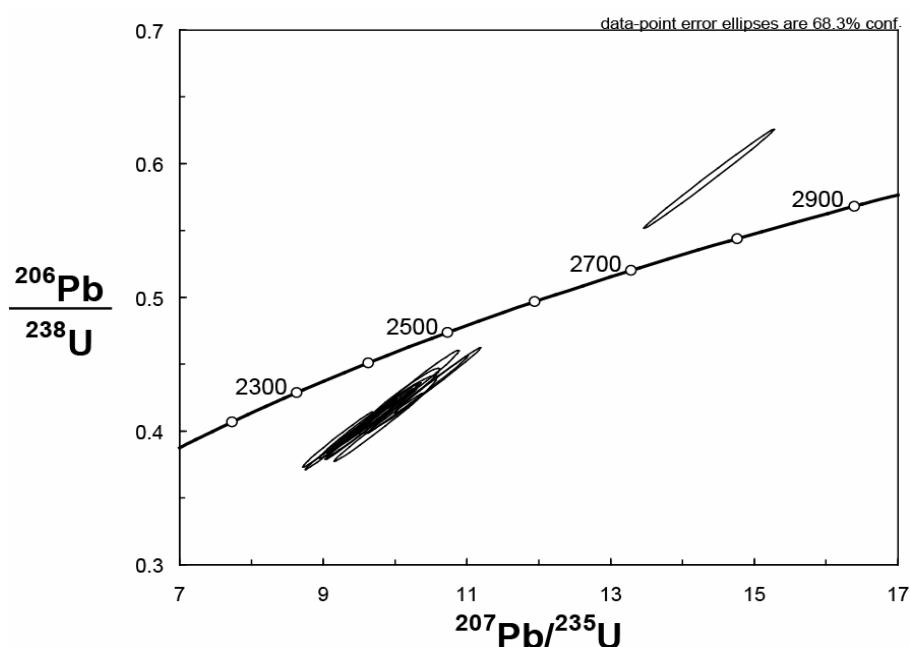

Age of deposition: > 2609 Ma

Age of metamorphism/migmatisation:  $2609 \pm 14$  Ma (upper-intercept age, MSWD 2.3, n = 16)

The zircons are quite small, 80–120 µm in length with aspect ratios of typically 1:1 to 1:1.5. They are commonly rounded with slightly scalloped edges, suggestive of partial resorption. All are completely homogeneous.

Thirty spots in 30 grains were analysed. One analysis with high common Pb was discarded. Ages that are < 10% discordant ( $n = 16$ ) range from  $2625 \pm 11$  Ma to  $2553 \pm 15$  Ma with U contents of 669–1302 and Th/U of 0.44–1.41. There is significant spread in the age data with ages trending toward a plateau around 2575 Ma. All sixteen analyses yield a poorly-defined age of  $2609 \pm 14$  Ma (upper-intercept age, MSWD 2.3,  $n = 16$ ).

The sample was collected from a migmatitic garnet-biotite schist with interlayered leucosome and more biotite-rich material of inferred sedimentary or volcanic origin. Given the homogeneous rounded morphology of the grains, the  $2609 \pm 14$  Ma age is interpreted as a recrystallisation event, probably recording the timing of migmatitisation, rather than recording any origin detrital or volcanic age.

**Figure 19.** 498803  $^{206}\text{Pb}/^{238}\text{U}$ - $^{207}\text{Pb}/^{235}\text{U}$  concordia diagram and inset  $^{207}\text{Pb}/^{206}\text{Pb}$  age plot.

#### 498864

Collector: Nigel Kelly

Lithology: Heterogeneous migmatitic biotite-felsic orthogneiss. Granodioritic to dioritic layer, possibly pre-dating the tonalitic phase (cut by tonalite in some outcrops), with minor leucosome

Location: Ujarassuit area 4

Locality: nmk2005-195, 64 48.696°N, -50 24.414°W

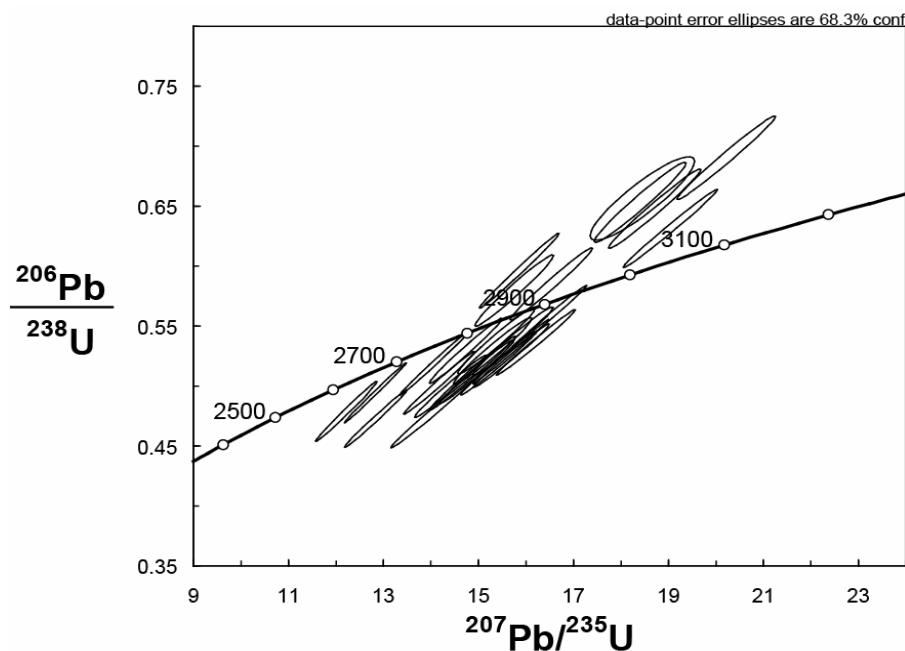

Aim: age of earliest phase of magmatism within the regionally dominant felsic orthogneiss

Age of emplacement  $\geq 2974$  Ma

The zircons are 150–250  $\mu\text{m}$  in length with aspect ratios typically 1:2 to 1:3, and commonly prismatic. All have well-defined oscillatory zonation, a few with large homogeneous cores.

Thirty spots in 29 grains were analysed. No grains showed significant common Pb. Ages that are < 10% discordant ( $n = 26$ ) range from  $2974 \pm 13$  Ma to  $2699 \pm 14$  Ma with U contents of 19–448 and Th/U of 0.10–0.57. There is a slight trend toward lower Th/U with decreasing age. The age data show significant spread with no obvious plateau defining a distinct population.

The sample was collected from a granodioritic to dioritic layer within a heterogeneous migmatitic biotite-felsic orthogneiss, representative of the dominant regional orthogneiss in Ujarassuit area 4. This granodioritic to dioritic variety is commonly cut by the tonalitic phase of this gneiss and is interpreted as representative of the earliest phase of magmatism represented in this multi-component gneiss. The age data does not clearly define the age of emplacement. It is likely that some of the 6 ages represent partial Pb-loss from older grains, though there is no morphological or chemical evidence to support this. A cluster of ages at c. 2930–2870 Ma may encompass the timing of emplacement. A minimum constraint on the timing of emplacement is given by the oldest near-concordant grain –  $2974 \pm 13$  Ma (< 4% discordant).

**Figure 20.** 498864  $^{206}\text{Pb}/^{238}\text{U}$ - $^{207}\text{Pb}/^{235}\text{U}$  concordia diagram.

**498877**

Collector: Nigel Kelly

Lithology: massive, weakly foliated felsic biotite orthogneiss with minor leucosome. Representative of the youngest phase of magmatism, post-dating the main gneissic fabric in the regionally dominant felsic orthogneisses

Location: Ujarassuit area 4

Locality: nmk2005-248, 64 49.638°N, -50 24.744°W

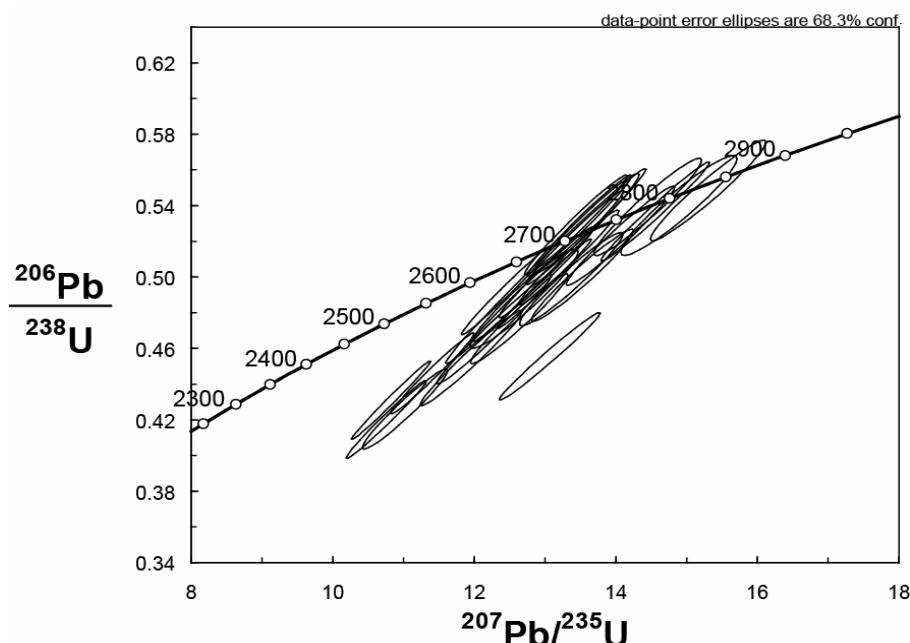

Aim: age of emplacement of youngest phase of magmatism in area 4

Age of emplacement:  $\geq$  c. 2825 Ma

The zircons are 50–150  $\mu\text{m}$  with aspect ratios typically 1:1 to 1:2.5, commonly prismatic. All have oscillatory zonation, a few with large sector-zoned cores.

Thirty spots in 29 grains were analysed. Two analyses with high common Pb were discarded. Ages that are  $< 10\%$  discordant ( $n = 26$ ) range from  $2845 \pm 31$  Ma to  $2672 \pm 14$  Ma with U contents of 28–1075 ppm and Th/U of 0.06–0.29. There is significant spread in the age data with no distinct plateau in ages.

The sample was collected from a massive, weakly foliated felsic biotite orthogneiss with minor leucosome. This is thought to be representative of the youngest phase of magmatism, post-dating the main gneissic fabric in the regionally dominant felsic orthogneisses. Unfortunately there is significant spread in the ages with no distinct correlation between ages, chemistry, and morphology. It is possible that ancient Pb-loss has affected grains of  $\geq 2780$  Ma. The two oldest grains are distinct high-U oscillatory-zoned cores that may be inherited. Ignoring these, the oldest near-concordant oscillatory-zoned core is  $2826 \pm 41$  Ma ( $< 0.9\%$  discordant), interpreted as the minimum timing of emplacement. This in turn gives a minimum constraint on the formation of the regional gneissic fabric.

**Figure 21.** 498877  $^{206}\text{Pb}/^{238}\text{U}$ - $^{207}\text{Pb}/^{235}\text{U}$  concordia diagram.

**498892**

Collector: Nigel Kelly

Lithology: Coarse-grained, intermediate composition foliated amphibolite of inferred volcanic origin.

Location: Ujarassuit area 4

Locality: nmk2005-264, 64 48.396°N, -50 24.912°W

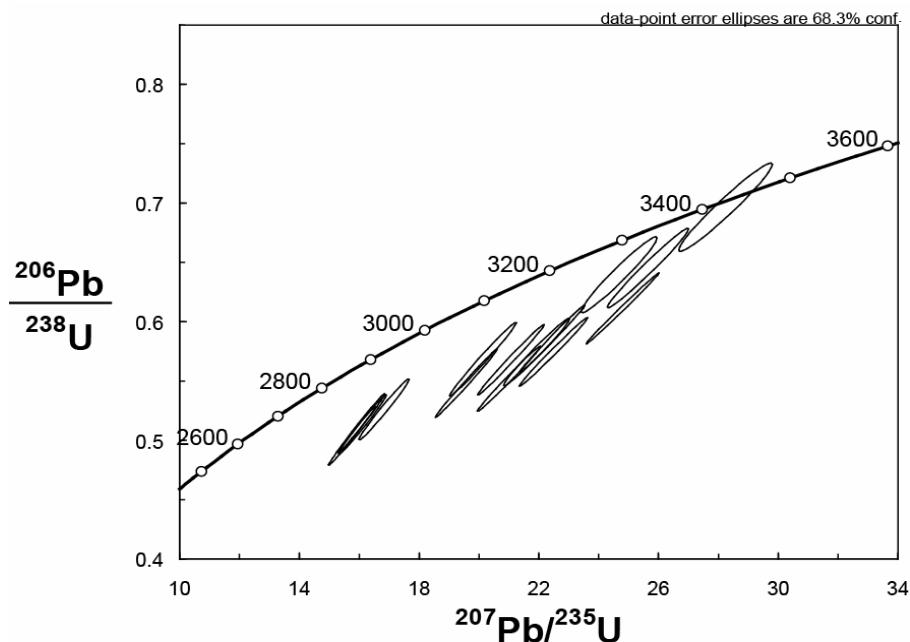

Aim: depositional age of volcanic supracrustal rocks

Age of deposition: ? c. 3400 Ma

The zircons are 50–150 microns long, with aspect ratios of 1:1 to 1:2 with stubby irregular shapes, consistent with a volcanic origin. Many have metamict cores, patchy zonation, and are heavily fractured. A few preserve relict oscillatory zonation.

Twenty-five spots in 25 grains were analysed. Two analyses with high common Pb were discarded. Ages range from c. 3440 Ma to 3029 Ma, though most are significantly discordant (> 5%). U contents range from 172–730 ppm and Th/U from 0.11–2.84. There is no significant correlation between age, chemistry, and morphology. The oldest 11 grains range from  $3440 \pm 8$  Ma to  $3228 \pm 16$  Ma, whereas the youngest three form a cluster at c. 3030 Ma, which may or may not reflect a real geological event.

The sample was collected from a coarse-grained, foliated amphibolite of intermediate composition and inferred to have a volcanic origin. The zircon morphologies (small, irregular grains) are consistent with a volcanic origin. The rock was evidently formed in the early part of the Mesoarchaean, though the exact depositional age is unclear. Given the spread in ages and cluster of ages at c. 3030 Ma, it seems likely that this sample has been affected by some Pb-loss. It is therefore difficult to assess the original depositional age, other than to say that this occurred prior to c. 3030 Ma. If the cluster of ages at c. 3400 Ma are close to the true depositional age, this would be an unusual result – supracrustal rocks of this age are otherwise unknown in the Nuuk region. However, we reiterate that the exact timing of deposition is not clear from the age data.

**Figure 22.** 498892  $^{206}\text{Pb}/^{238}\text{U}$ - $^{207}\text{Pb}/^{235}\text{U}$  concordia diagram and inset  $^{207}\text{Pb}/^{206}\text{Pb}$  age plot.

#### 498921

Collector: Nigel Kelly

Lithology: Felsic-intermediate biotite orthogneiss with minor leucosome

Locality: nmk2005-336, 64 45.918°N, -50 32.310°W

Location: Ujarassuit area 5

Aim: emplacement age of felsic orthogneiss dominant in Ujarassuit area 5

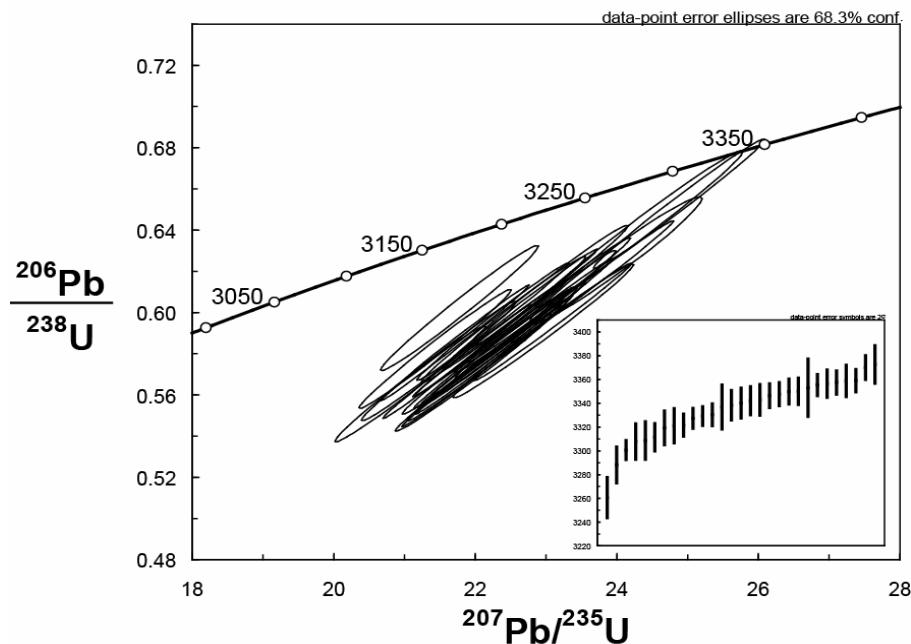

Age of emplacement:  $\geq$  c. 3373 Ma

The zircons are 100–200  $\mu\text{m}$  in length with aspect ratios typically 1:1 to 1:2.5, and commonly prismatic. The majority show oscillatory zonation, though some show patchy zonation and a few are homogeneous.

Thirty spots in 30 grains were analysed. No analyses had significant common Pb. Ages that are  $< 10\%$  discordant ( $n = 29$ ) range from c. 3373 to 3271 Ma with U contents of 42–620 ppm and Th/U of 0.02–1.21. There is no significant correlation between age, chemistry, and morphology. There is significant spread in the age data with no distinct plateau in ages.

The sample was collected from a felsic to intermediate biotite orthogneiss with minor leucosome, representative of the dominant orthogneiss in Ujarassuit area 5. The spread in ages from c. 3373 to 3271 Ma is probably the result of some ancient Pb-loss, though the timing of this event is not clear from the data. The oldest near-concordant grain –  $3373 \pm 16$  Ma ( $< 7.2\%$  discordant) – gives a minimum constraint on the timing of emplacement. This unit was previously mapped (Chadwick and Coe 1988) as Nûk gneiss, though it is clearly

significantly older. If c. 3370 Ma represents an emplacement age for this rock, this is unusual age for the Nuuk region. The only other thermal event recorded around this time is the emplacement of the Ameralik dyke swarms at c. 3510 to 3260 Ma (Nutman et al. 2004).

**Figure 23.** 498921  $^{206}\text{Pb}/^{238}\text{U}$ - $^{207}\text{Pb}/^{235}\text{U}$  concordia diagram and inset  $^{207}\text{Pb}/^{206}\text{Pb}$  age plot.

#### 498937

Collector: Nigel Kelly

Lithology: Felsic biotite orthogneiss with minor leucosome

Location: Ujarassuit area 5

Locality: nmk2005-351, 64 46.008°N, -50 29.664°W

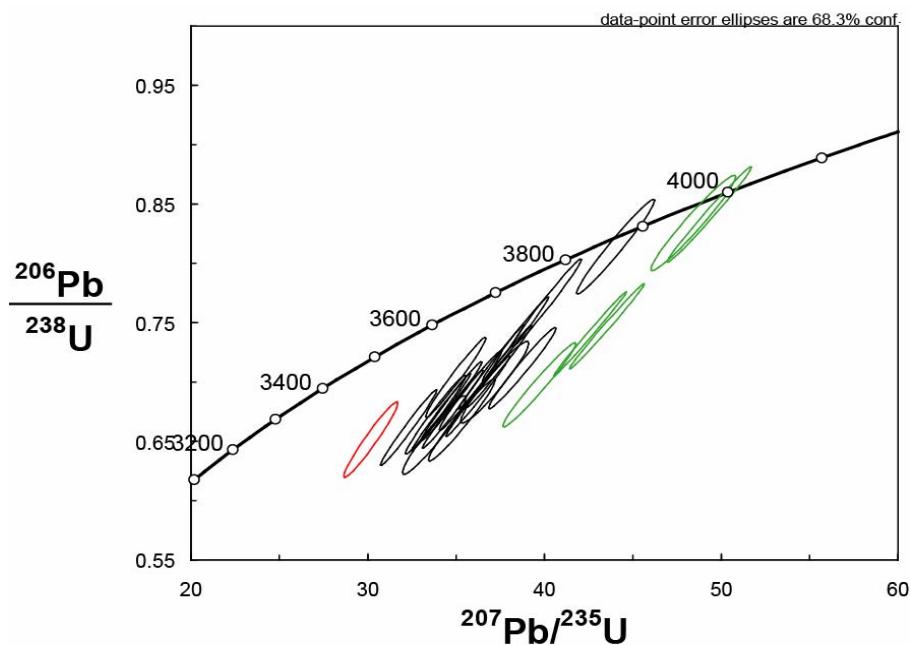

Aim: age of emplacement of regionally dominant felsic orthogneiss in Ujarassuit area 5

Age of emplacement:  $3872 \pm 43$  Ma (upper-intercept age, MSWD 2.5, n = 12)

The zircons are 100–300 µm in length with aspect ratios typically 1:2 to 1:3, and commonly prismatic. Many of the grains show very distinct oscillatory zonation, some with broad homogeneous rims. A few grains show only relict oscillatory zonation and some are completely homogeneous.

Thirty spots in 27 grains were analysed. One analysis had significant common Pb and was discarded. Ages that are < 10% discordant (n = 23) range from c. 4000 to 3640 Ma with U contents of 36–387 ppm and Th/U of 0.15–0.97. There is no significant correlation between age, chemistry, and morphology. There is a cluster of ages at c. 3870 Ma (based on an upper-intercept of  $3872 \pm 43$  Ma (MSWD 2.5, n = 12) with a spread toward younger ages, the youngest being a homogeneous rim analysis. Five relatively older grains give an upper-intercept age of  $4009 \pm 18$  Ma (MSWD 1.4, n = 5).

The sample was collected from a felsic biotite orthogneiss with minor leucosome representative of the dominant felsic orthogneiss in Ujarassuit area 5. This was previously mapped as a part of the Eo- to Palaeoarchaean group of orthogneisses, which is also evident from the age data presented here. The precursor to this orthogneiss was likely emplaced at c. 3870 Ma with zircon grains partially affected by Pb-loss. A single homogeneous rim analysis giving an age of c. 3644 Ma may reflect a known regional metamorphic/migmatitic event at this time: granulite facies metamorphism of Eoarchaean gneisses is known to have occurred at c. 3650 Ma regionally (Nutman et al. 1996). Interestingly there are five very old grains in this sample, giving a reasonable upper-intercept age of  $4009 \pm 18$  Ma. Zircon older than 3900 Ma are very rare in the Nuuk region.

**Figure 24.** 498937  $^{206}\text{Pb}/^{238}\text{U}$ - $^{207}\text{Pb}/^{235}\text{U}$  concordia diagram and inset  $^{207}\text{Pb}/^{206}\text{Pb}$  age plot.

Aim: age of deposition of volcanic supracrustal rock

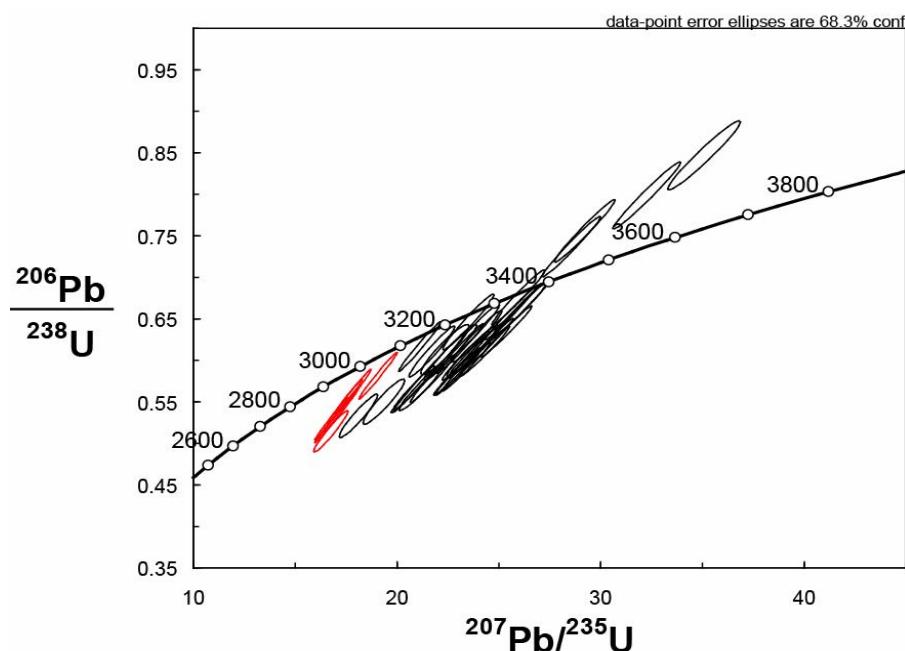

Age of volcanic deposition: c. 3400 Ma

Age of metamorphism:  $3056 \pm 5$  Ma (MSWD 1.18, n = 5 of 39)

The zircons are 80–150 µm in length with aspect ratios of 1:1 to 1:2, commonly irregular to prismatic. All have the same distinct morphology. They have CL-bright homogeneous cores and CL-dark thin rims (up to 30 µm wide). The unusual contrast in CL and the consistency in morphology of all grains suggests a common origin for these grains (eg. formed in the same volcanic episode).

Forty-eight spots in 44 grains were analysed. Five analyses had significant common Pb and were discarded. Concordant ages ( $n = 39$ ) range from  $3472 \pm 26$  Ma to  $3050 \pm 13$  Ma with U contents of 18–118 ppm and Th/U of 0.01–2.37. There is a strong correlation between decreasing Th/U with decreasing age. Five analysis of rims give a fairly well-defined age of  $3056 \pm 5$  Ma (upper-intercept age anchored at the origin, MSWD 1.18,  $n = 5$ ). All have relatively high-U (88–132 ppm) and low Th/U (0.01–0.04), consistent with a metamorphic origin. The remaining analyses of homogeneous, oscillatory-zoned, and patchily-zoned cores form no distinct plateau in ages, but rather a range from c. 3472 to 3094 Ma.

The sample was collected from a garnet-bearing amphibolite of inferred volcanic origin in the Ujarassuit area 5. The range in ages, despite the similarity in morphology of all grains, and the strong correlation between Th/U and age are consistent with Pb-loss of the original zircon population during a later thermal event. The most concordant old grain is  $3417 \pm 16$  Ma (< 4.6% discordant), which is probably close to the original depositional age of at least part of the supracrustal belt in Ujarassuit area 5 (see Figs 1 and 4). The trend in younger ages toward c. 3050 Ma, corresponding decrease in Th/U, and the high-U, low Th/U population of rim analyses at  $3056 \pm 5$  Ma suggest that a thermal event at this time may have been responsible partial Pb-loss from the original volcanic population. This may be related to emplacement of regional felsic orthogneisses of this age (eg. Nûk gneisses, c. 3010–3070 Ma).

**Figure 25.** 498945  $^{206}\text{Pb}/^{238}\text{U}$ - $^{207}\text{Pb}/^{235}\text{U}$  concordia diagram.

## Acknowledgements

This project was financially supported by the Bureau of Minerals and Petroleum (BMP), Nuuk. The following people are acknowledged for involvement in analytical work and discussion of results: Ali Polat and Carlos Ordonez (University of Windsor), Dave Coller (EraMaptec), Matilde Rink Jørgensen, Rasmus Haugaard Nielsen, Louise Josefine Nielsen, Peter Venslev, Daniel Weilandt (University of Copenhagen), Peter Appel, Adam A. Garde, Carsten Guvad, Karen Merete Henriksen, Jørgen Kystol, Hanne Lamberts, Eric A. Nielsen, Agnete Steenfelt, Henrik Stendal, Bo Møller Stensgaard (GEUS).

## **Appendix 1: Tabulated LA-SF-ICPMS zircon U-Pb age data**

Zircon U-Pb age data were collected using a NewWave Research/Merchantek UP213 laser and Element2 sector-field inductively coupled plasma mass spectrometer at GEUS. Analysis numbers referred to images of zircon grains used to select analysis sites. Abbreviations are as follows: \* – analysis used in age calculation quoted in the text, Disc. – % discordance, gr – grain, hi U – high uranium, hom – homogeneous, osc – oscillatory zoned, pat – patchy, rho –  $^{235}\text{U}/^{207}\text{Pb}$ - $^{238}\text{U}/^{206}\text{Pb}$  error correlation, sec – sector, 204bdl – 204Pb was below the detection limit.
